"A novel method for detecting the onset of experimental effects in visual world eye-tracking (and other time-series data)"

"Determining the onset of experimental effects in time-series data is important in psycholinguistics, because it allows for a more precise evaluation of accounts of the timecourse of different types of information during language processing, as well as their impact on predictive computations. We propose a novel method that addresses these short-comings, and that allows researchers to more accurately detect the onset of experimental effects and compare them between experimental conditions and participant groups"
